Summary

- 1. This report provides an updated integrated stock assessment of Patagonian toothfish *Dissostichus eleginoides* in Falkland Islands waters, using data up to the end of 2023.
- 2. The initial spawning stock biomass SSB_0 was estimated at 25,942 tonnes, and the current spawning stock biomass SSB_{2023} at 12,728 tonnes; both higher than in the 2023 assessment (by 5.8 and 10.3%, respectively).
- 3. The ratio of current spawning stock biomass to initial spawning stock biomass (SSB₂₀₂₃/SSB₀) was estimated at 0.491, slightly higher than in the 2023 assessment (by 5.1%) but comparable to the 2022 assessment estimate. According to established harvest control rules (HCR), the SSB₂₀₂₃/SSB₀ ratio places the stock in the *expansion range*.
- 4. Projections from the current model indicated that the SSB/SSB₀ ratio will drop and remain in the *target range* during 2029-2045.
- 5. Based on HCR, the recommendation is to maintain toothfish annual TAC in the longline fishery at its current level of 1,040 tonnes.

1. Introduction

Patagonian toothfish (*Dissostichus eleginoides*; hereafter, toothfish) is a long-lived slow-growing species found on the shelves and slopes of South America and around the sub-Antarctic islands of the Southern Ocean. In Falkland Islands waters, toothfish spawn on the slopes of Burdwood Bank at ~1000 m depth, with a minor spawning peak in May and a prominent peak in July-August (Laptikhovsky *et al.* 2006). The eggs, larvae, and small juveniles (<10 cm TL) develop and grow in epipelagic layers of the Falkland Current, with early juveniles of 10-12 cm TL (<1 year old; Lee 2017) occurring on the Patagonian shelf at depths ~100 m. Immature toothfish remain on the shelf for 3-4 years and then undertake a characteristic ontogenetic migration into deeper waters where adults reside and spawn (Arkhipkin and Laptikhovsky 2010).

The Falkland Islands toothfish longline fishery began in 1992 as an exploratory fishery and became an established fishery in 1994 (Laptikhovsky and Brickle 2005). Fishery used the 'Spanish' longlining system (with a few vessels using the Mustad Autoline system in the early years) until the 'umbrella' system was introduced in 2007 to reduce the loss of hooked toothfish to depredation. The umbrella system consists of hooks set in clusters, with an umbrella of buoyant netting attached above each cluster. The umbrella floats above the cluster whilst the gear is on the seabed but folds over the cluster and hooked fish during hauling, preventing depredation (Brown *et al.* 2010). Following initial trials in 2007, all vessels operating in the Falkland Islands longline fishery adopted the umbrella system by 2008.

Besides targeted longline fishery, toothfish are bycatch in the shelf-based (<400 m depth) finfish and calamari trawl fisheries. In the finfish fishery, toothfish is a commercially valuable bycatch; in the calamari fishery, toothfish are typically discarded due to the small size of the specimens (20-30 cm TL). These fisheries exploit different parts of the toothfish population in distinct areas: longlining occurs on the deep-water slope, finfish trawling on the shelf primarily north and west of the Falkland Islands, and calamari trawling on the shelf south and east of the Falkland Islands (Figure 1).

This report presents an updated Bayesian integrated stock assessment for toothfish in Falkland Islands waters, using data up to the end of 2023.

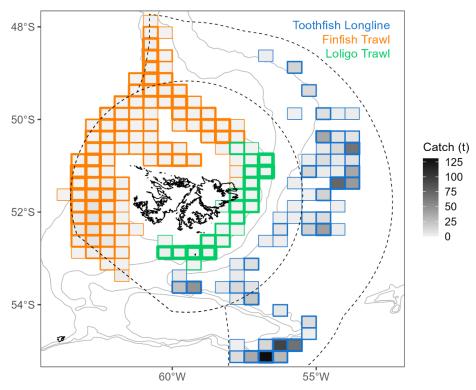

Figure 1. Distribution of toothfish catch and effort per fishery in 2023. The thickness of grid lines is proportional to vessel-days. Grey-scale is proportional to toothfish catch biomass.

1.1. Stock structure and assumptions

A long-term research programme investigating the stock structure of toothfish on the Patagonian Shelf revealed complex patterns (Lee 2023). Research results indicate high levels of spatial-temporal variability in the extent of connectivity during the early life-history phases of egg and larval dispersal. Recruitment on the Falkland Islands Shelf arises from both Burdwood Bank and southern Chile spawning areas. It is proposed that high recruitment pulses are dominated by input from the Burdwood Bank spawning contingent. These pulses show strong spatial-temporal variability. Stable recruitment at lower levels occur from the southern Chile spawning contingent, where they are retained on the western shelf of the Falkland Islands. Further, evidence of connectivity across the region through the active migration of adults appears to occur on a relatively small scale. Current results demonstrate that the stock structure arising from the retention of mixed contingents across the Falklands Shelf remains discrete (within the Falkland Islands Conservation Zone) until the adult life-history stages. Therefore, considering the currently available information, for this assessment we assumed that there is one discrete toothfish stock present in Falkland Islands waters.

2. Methods

The stock assessment was undertaken using an integrated age-structured model implemented in CASAL (Bull et al. 2012) version v2.30-2016-05-01 rev. 5470. The model assumes a single homogenous area, but the spatial heterogeneity of the population is represented by three geographically distinct commercial fisheries (longline, calamari trawl, and finfish trawl) and their gear-specific selectivity and fish availability (i.e. fleets-as-areas approach). The longline fishery is further split into two distinct fisheries according to gear type (Spanish-system and umbrella-system longline) to accommodate for different catchability between the two.

2.1. Model updates

Compared to the previous assessment (Skeljo *et al.* 2023), this assessment was updated with (a) catch and effort data for the umbrella-system longline fishery in 2023, (b) catch data for the finfish and calamari trawl fisheries in 2023, (c) biological data (size-structure and maturity) for all fisheries and research surveys in 2023, (d) additional age readings for 2021, and e) tag release data in 2022 and tag recapture data in 2023.

2.2. Data

Several datasets were used to inform the assessment, either as observations or input parameters (Figure 2). CPUE, catch-at-age and tag-recaptures are observations, i.e. appear in the objective function and are used to fit the model. Parameters of the length-at-age relationship, length-weight relationship and maturity curve are estimated outside the model and then treated as fixed parameters within the model.

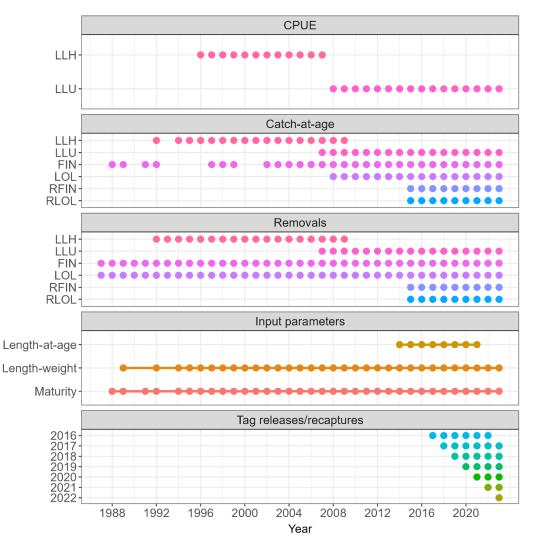

Figure 2. Data used to inform the assessment model. LLH - Spanish-system longline, LLU - umbrella-system longline, FIN - finfish trawl, LOL - calamari trawl, RFIN - groundfish survey, RLOL - calamari pre-season survey. Data used to calculate input parameters were pooled across years. Tag release years are on the y-axis, and tag recapture years are on the x-axis.

Catch-per-unit-effort (CPUE)

Although CPUE data were available for all four fisheries, only longline CPUE was used as a relative abundance index in the model; a decision motivated by the inconsistency of toothfish CPUE in trawl fisheries, where toothfish bycatch may change due to factors other than stock abundance (e.g. fisheries switching targets or areas). Longline CPUE data were divided between the Spanish and umbrella systems to allow for different catchability between the two, as was previously observed (Brown *et al.* 2010). The transition from the Spanish to the umbrella system occurred in 2007-2008.

For the Spanish-system longline fishery, the catch and effort data were available only aggregated per day (the fishery predates the use of electronic logbooks). 95 daily catch reports from remote areas (outside the region 47°W - 70°W and 40°S - 57°S) were excluded from the analysis. These records belong to the early years of the fishery (1998-2002) when presumably more exploratory fishing took place.

For the umbrella-system longline fishery, the catch and effort data were available per line (electronic logbook data). Since the onset of the umbrella system, the fishery was dominated by a Falkland Islands vessel (*CFL Gambler*, replaced by *CFL Hunter* in 2017), occasionally assisted by up to two chartered Chilean vessels. None of the chartered vessels participated in the Falkland Islands fishery in more than two years since 2007, resulting in inconsistent CPUE data. Moreover, at least one of the chartered vessels had restrictions imposed on its fishing practice (e.g. limit on the number of fishing days in the 'best' fishing grounds) that were not in place for the Falkland Islands vessel. Because of the above, we decided to use only the Falkland Islands vessels CPUE as an index of abundance. With a similar goal, data from dedicated tagging trips and longlines set at depths <600 m were excluded from the analysis; tagging trips because part of the actual catch was unreported (released fish), and shallow-water sets because these were experimental fishing to collect brood stock for the toothfish rearing facility (commercial longlining is prohibited at depths <600 m).

CPUE was calculated from the cleaned data as reported toothfish catch in kg-per-hook per day (Spanish system) or kg-per-umbrella per line (umbrella system). Finally, CPUE was standardised using a generalised linear mixed modelling approach (GLMM), providing a time series of CPUE values as relative abundance indices (Appendix 1). The observation error of the CPUE indices was accounted for in the assessment model via the coefficient of variation (CV) estimates obtained directly from a GLMM standardisation. To account for any additional variance on top of observation error, that may arise from the differences between model simplifications and real-world variation, a process error CV = 0.1 was assumed. The CPUE indices were assumed log-normally distributed about the model-predicted vulnerable biomass via a catchability parameter.

Catch-at-age (CAA)

Age readings used for the assessment were restricted to otoliths sampled in 2014-2021; these were processed and aged at the Falkland Islands Fisheries Department (FIFD) and were considered the most reliable toothfish age estimates available (Lee 2014, 2015, 2016, 2017, 2018, 2019, 2020; Lee and Le Luherne 2023). Since the last assessment (Skeljo *et al.* 2023), an additional 225 age readings belonging to otoliths collected in 2021 became available; otoliths collected in 2022 and 2023 are yet to be processed. In total, 3,089 toothfish age estimates belonging to longline fisheries and 3,170 age estimates belonging to trawl fisheries were used to construct two corresponding age-length keys: ALK_{LONGLINE} and ALK_{TRAWL}. Next, the length-frequency distribution of 149,331 toothfish randomly sampled in 1988-2023 was split between the corresponding fisheries or surveys. Age was assigned to each fish by the conditional probability of the appropriate age-length key: ALK_{LONGLINE} for longline fisheries and ALK_{TRAWL} for calamari fishery, finfish fishery, and surveys. Ages \geq 31 years were assigned to a plus group. Then, fish counts-at-age were catch-raised per haul (i.e. multiplied by the catch/sample weight ratio in each observed haul), aggregated per year and fishery, and converted to proportions-at-age. For calamari trawl fishery, CAA data up to 2008 were considered unrepresentative and thus excluded from the analysis (Skeljo and Winter 2020, 2021). The ageing error was accounted

for by deriving an error misclassification matrix from a normal distribution with CV = 0.1. The CAA data were assumed independently multinomially distributed about the model-predicted CAA.

A consideration in integrated models is to ensure that the observations are given appropriate weights in the objective function. The CAA data were weighted via effective sample sizes, estimated by a two-stage weighting approach: in stage 1 the weights appropriate for the observation error are assigned outside the model, and in stage 2 those weights are adjusted within the model to allow for process error (Francis 2011). In our assessment, in stage 1 the effective sample sizes were calculated based on the data fit to the multinomial distribution, using the function *neff.obs* from R package *DataWeighting* (Francis 2013). The initial model fit was then run, and the information from that run was used in the stage 2 adjustment of the effective sample sizes, multiplying them by a weighting factor calculated as:

$$w_j = \frac{1}{var_i \left[(O_{ij} - E_{ij}) / \sqrt{(v_{ij} / N_{ij})} \right]}$$

where N_{ij} is the number of multinomial cells, O_{ij} is the observed proportions for age class *i* in year *j*, E_{ij} is the expected proportions, and v_{ij} is the variance of the expected age distribution (Method TA1.8 in Francis 2011). The model was then re-run with the adjusted effective sample sizes (Table 2).

<u>Removals</u>

Removals accounted for the reported catches in the Falkland Islands waters, IUU catches in the Falkland Islands waters and catches lost to undetected whale depredation.

Catch reports from all available years for the four fisheries and two research surveys were used, starting in 1987. Trawl catch reports without licence information were considered calamari trawls if the dominant species in the catch was *Doryteuthis gahi* and finfish trawls otherwise.

No information on IUU fishing within the Falkland Islands waters was available; therefore, we utilized the data for the Antarctic region (Agnew *et al.* 2009), which gives estimates of IUU catches as a proportion of reported catches in 1980-2003. For later years, we took grey-literature estimations (e.g. CCAMLR Secretariat 2010) that IUU fishing decreased significantly in the southern oceans and assumed IUU catches equal to 5% of the reported catches in the Falkland Islands waters.

Whale depredations are included in longline catch reports when they are evident as toothfish hauled up damaged or destroyed by bite-marks. However, toothfish taken entirely by whales before hauling are not seen and accounted for in the catch reports. To quantify this cryptic depredation, Winter and Pompert (2016) developed a model-differencing algorithm between catches predicted from all observer-monitored longlines and catches predicted only from observer-monitored longlines without signs of whale depredation. Models included parameters: longline position, fishing depth, year, month, number of hooks, and soak time. The model-difference could then be projected onto all commercial longlines to estimate the amount of toothfish lost. The algorithm has recently been revised by modelling Spanish-system and umbrella-system longline fishing separately, as for the stock assessment, and by projecting the depredation ratios of the models rather than the models themselves, which improved the avoidance of outlier extrapolations.

Adding the reported catches, assumed IUU catches, and estimated whale depredation resulted in total removals used in the assessment model (Figure 3). The removals are treated as input parameters in CASAL and were assumed known without error.

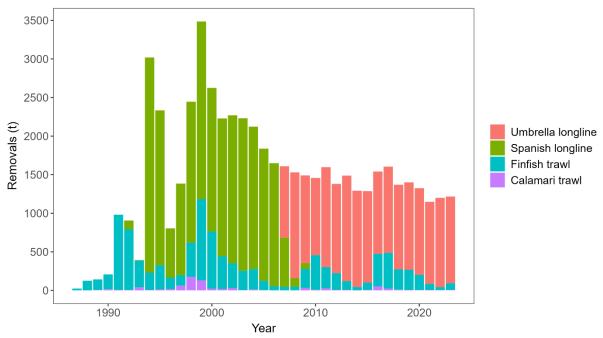

Figure 3. Toothfish removals in FCZ from 1987 to present, per fishery. Removals in trawl fisheries equal the reported catches. Removals in longline fisheries equal the sum of reported catches, assumed IUU catches and estimated depredation.

Length-weight relationship

The length-weight relationship was calculated as $W = aL^b$ based on the length and weight measurements of 42,544 toothfish sampled randomly by the observers from commercial catches in 1989-2023. Length-weight parameters are given in Table 3.

Von Bertalanffy growth

The length-at-age relationship was described by the von Bertalanffy growth model $L = L_{inf}(1 - e^{-k(age-t_o)})$ based on age estimates and length measurements of the combined 3,089 + 3,170 = 6,259 toothfish sampled randomly by observers from commercial catches in 2014-2021. Von Bertalanffy growth model parameters are given in Table 3.

Natural mortality

Natural mortality (M) was assumed to be 0.165 (Payne *et al.* 2005) and time- and age-invariant. Even though M would ideally be estimated within the model, there is likely not enough information in the available observations to do so reliably; all toothfish assessments done in CCAMLR waters assume a fixed M value (Earl and Readdy 2023; Readdy and Earl 2023; Masere and Ziegler 2023; Massiot-Granier *et al.* 2023a, 2023b; Mormede *et al.* 2023). Model sensitivity to different assumed M values was explored by Skeljo *et al.* (2022).

<u>Maturity</u>

A maturity-at-age vector was based on the maturity stage data estimated by observers for the 167,530 toothfish sampled randomly from commercial catches during 1988-2023. Maturity was scored on an 8-point scale, and toothfish are considered mature from stage 3 (Laptikhovsky *et al.* 2006). However, mature toothfish occasionally enter a 'resting' stage, and they can skip annual spawning (Collins *et al.* 2010, Boucher 2018). While in this resting stage, the gonads look very similar macroscopically to stage 2 gonads that are considered immature. Analysis of the maturity data strongly indicated some older fish were erroneously assigned immature (stage 2) when observed. To address this inaccuracy, a generalized additive model (GAM) was used to predict the expected number of older fish at stage 2,

and maturity data were corrected accordingly (Farrugia and Winter, 2018). Finally, instead of the more typical logistic function, the maturity ogive was fitted using GAM, resulting in a maturity-at-age vector with the proportion of mature fish in each age class from 1 to 31+ (plus group). The maturity-at-age vector is given in Table 3.

Tag releases and recaptures

The tagging programme for the Falkland Islands toothfish commenced in 2016, aiming to improve our understanding of toothfish movement patterns within the region. The initial goal of tagging 3000 fish was achieved during four tagging research surveys onboard the longliner in 2016-2018. In addition to surveys, observers have been tasked to tag an average of 25 toothfish per week during their trips onboard the longliner. However, the tagging programme largely relied on dedicated research surveys; in their absence, the number of tagged toothfish declined considerably in 2019-2020. In response, a 4-year extension of the tagging programme has been recommended (Lee and Skeljo 2020) and followed up by renewed tagging efforts since 2021 (Skeljo and Pearman 2021, Nicholls and Raczyński 2023, Le Luherne and Peruzzo 2023) with a goal of tagging ~1000 longline-caught fish annually, i.e. one fish per tonne of TAC. Since 2016, 6692 toothfish have been tagged on the High Seas (North Scotia Ridge) in 2023 to improve our understanding of toothfish stock connectivity within the region. Under the current assumption of a discrete toothfish stock in the Falkland Islands waters (Lee 2023), the potential future recaptures of fish tagged on the High Seas would not be used when fitting the assessment model.

Table 1. Number of longline tag releases within FCZ, tag recaptures within FCZ, and tag recaptures outside FCZ (in brackets). Numbers with grey shading were used in the assessment (i.e. within-year recaptures and recaptures after six years at liberty were excluded). Recaptures outside FCZ were used when calculating the tag emigration rate but not when fitting the assessment model to the tag recapture data.

* Additional 536 toothfish were tagged on the High Seas in 2023.

The spatial distribution of toothfish tag releases, recaptures, and longline fishing effort is given in Figure 4; it shows that (a) the spatial extent of longline fishing effort remained consistent between 2016-2023, (b) tag releases were well spread across the fishing area in high-release years (2017, 2018, 2021, 2022) compared to a more localised spread in low-release years (2019, 2020), and (c) spatial overlap between fish releases and their subsequent recaptures was high.

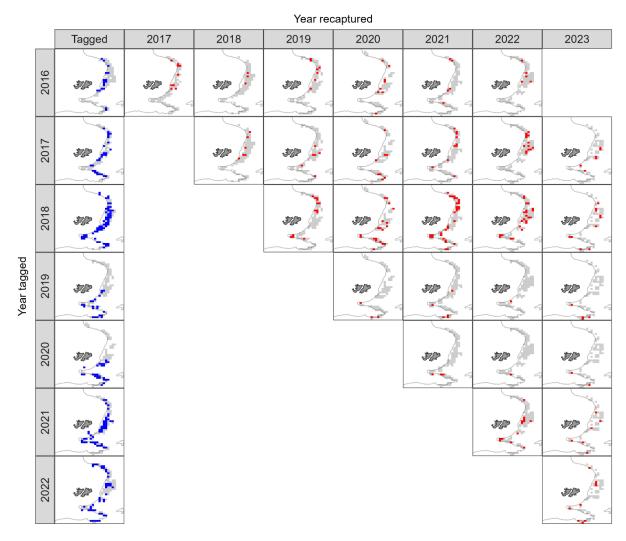

Figure 4. Spatial distributions of toothfish tag releases in FCZ in 2016-2022 (blue) and recaptures in FCZ in 2017-2023 (red); grey shading denotes the distribution of longline fishing effort for each year. Recaptures after six years at liberty were excluded from the model and the plot. Cells correspond to locations where at least one tagged fish was released (blue) or recaptured (red) or where at least one longline was hauled (grey).

The current assessment used the data on longline-caught toothfish tag releases in 2016-2022 and their subsequent recaptures by longline in 2017-2023 (Table 1). Within-year recaptures were excluded from the model to restrict recapture data to tagged fish that had sufficient time to mix with the untagged population, at least at a local population level. The CASAL modelling framework allowed the specification of several tag-related parameters, i.e. initial tag-release mortality, tag-related growth loss, tag detection rate, and tag shedding rate. These parameters were obtained from the literature or estimated outside of the stock assessment model and then used as fixed input values in the assessment.

Initial tag-release mortality was assumed to be 10% (Agnew *et al.* 2006), effectively reducing the number of tagged fish in the population at the time of tagging. Tagging was assumed to result in a retardation of growth in individual toothfish equivalent to half a year of zero growth immediately after tagging (Parker *et al.* 2013). The tag detection rate in the longline fishery was assumed to be 100% due to the high observer coverage (~50%), an excellent record of cooperation with a sole vessel operating in the fishery since 2017, and the fact that each fish is handled individually by several crewmembers while un-hooked and processed.

All tagged toothfish in 2016-2023 have been double-tagged, with a large and a small dart tag. By 2023, 41 double-tagged fish were recaptured with only large tags and 19 with only small tags remaining, allowing the estimation of tag-shedding rates. Tag shedding rates were calculated following the approach outlined by Dunn *et al.* (2011) and Ziegler (2017) but adapted here to accommodate non-identical tags. The instantaneous shedding rate of large tags was $\lambda_1 = 0.0177$ and of small tags $\lambda_2 = 0.0354$. Since the CASAL algorithm requires a tag shedding rate for a single-tagged fish only, tag shedding rates for double-tagged fish had to be approximated by a single-tag shedding rate, estimated as $\lambda_s = 0.0029$. However, the approximation proved adequate only when the available recapture data were restricted to fish recaptured after ≤ 6 years at liberty (for details see Dunn *et al.* 2011). Since our tagging programme is recent, the only case of recaptures after >6 years at liberty occurred in 2023 for fish tagged in 2016 (a single fish recaptured after 7 years; see Table 1); these data were excluded from the model to allow for the above-mentioned approximation and do not appear in corresponding plots throughout the report.

Emigration of tagged fish out of the assessed area can violate the assumptions of tag recapture models used in the assessment and result in biomass and stock status being over-estimated. We estimated the emigration rate of toothfish from Falkland Islands waters based on the tag recaptures that occurred inside and outside of the FCZ, following the approach of Burch *et al.* (2017). For the recaptures outside the FCZ, we relied on the reporting by fishing fleets operating in these regions, specifically through collaborative work with Chile and the High Seas Korean fleet. The approach of Burch *et al.* (2017) requires the knowledge of annual harvest rates (i.e. catches and vulnerable biomass) both inside and outside of the FCZ; given the lack of reliable information on overall harvest rates outside the FCZ, we assumed them equal to inside the FCZ. Tag reporting was assumed to be 50% outside the FCZ, compared to 100% within the FCZ. The tag emigration rate was estimated at λ_M = 0.0451; the tag shedding parameter supplied to CASAL (λ_S) was increased by the value of the emigration rate, providing a simple yet effective approach to correct for the effects of emigration (Burch *et al.* 2017).

The numbers-at-length of toothfish tagged each year, by 10 cm length bin, were used as fixed input in the assessment model. The numbers-at-length of toothfish recaptured each year for each release year, by 10 cm length bin, were used as observations to fit the model. Besides releases and recaptures, the model required the numbers scanned at length (i.e. numbers of fish caught and inspected for a possible tag) in each recapture year; as detection was assumed 100% this was derived by disaggregating the total annual catch in numbers into 10 cm length bins, using the random length-frequency samples from the fishery observer records. For each recapture year, the recaptures-at-length from each release year t were fitted, in 10 cm length bins, using a robust binomial log-likelihood:

$$-LL = \sum_{i} \left[\log(n_i!) - \log\left((n_i - m_i)!\right) - \log(m_i!) + m_i \log\left(Z\left(\frac{M_i}{N_i}, r\right)\right) + (n_i - m_i) \log\left(Z\left(1 - \frac{M_i}{N_i}, r\right)\right) \right]$$

where n_i is the number of scanned fish in length bin *i*, m_i is the number of recaptured fish from release year *t* in length bin *i*, N_i is the expected number of fish in length bin *i* in the available population (tagged and untagged), M_i is the expected number of fish in length class *i* in the available population that have the tag from release year *t*, and Z(x,r) is a robustification function defined as:

$$Z(x,r) = \begin{cases} x \text{ where } x \ge r \\ r/(2-x/r) \text{ otherwise} \end{cases}$$

where r is a non-negative robustification constant; a default value of r = 1e-11 was used in the assessment.

The default assumption in the assessment is that the numbers of recaptures are independent between release years and between length bins and follow a robust binomial distribution. There is evidence

that some (probably most) tag-recapture datasets are over-dispersed; they are more variable than expected from the above assumptions and thus should be down-weighted (Francis 2016). CASAL provides parameter ϕ as an informal means of allowing for over-dispersion, with the log-likelihood of tag-recapture data being divided by ϕ . The default is $\phi = 1$; setting $\phi > 1$ implies over-dispersion and down-weights the data (Francis 2016). In the current assessment, the procedure was to use the default $\phi = 1$ in the initial model run and use the initial MPD model fit to calculate over-dispersion ϕ_j for each tagging event *j* from its *i* recapture events as:

$$\Phi_j = var\left(\frac{O_{ij} - E_{ij}}{\sqrt{E_{ij}}}\right)$$

where O_{ij} was the observed number of recaptures and E_{ij} was the estimated number of recaptures. Over-dispersion terms for each of the release years were then combined by taking the geometric mean, and the model was re-run with the log-likelihood of tag-recapture data modified by dividing with ϕ (Table 2).

As both CAA and tag-recapture data had to be reweighted, the reweighting was applied first to the CAA data, then to the tag-recapture data (i.e. in successive MPD model runs).

Table 2. Weighting factors (w) used to adjust effective sample sizes of catch-at-age data, and the over-dispersion parameter (ϕ) used to weight tag-recapture data.

2.3. Model setup

Population dynamics

Toothfish population dynamics were described by a Bayesian age-structured model, with age classes from 1 to 31+ years, the last being a plus group. It is a single-sex, single-area, multi-fishery model with an annual cycle divided into three time-steps. Recruitment, fishing mortality from all concurrent fisheries, tag releases and recaptures, and the first half of the year's natural mortality occur in time step 1; spawning and the second half of natural mortality in time step 2; and ageing in time step 3.

Since both fishing and natural mortality occur in time step 1, the process was to apply half time step's natural mortality, then fishing mortality instantaneously, then the remaining half of the time step's natural mortality.

Recruitment to the population was calculated by multiplying average recruitment (RO) with estimated year class strength (YCS) and a stock-recruitment relationship. Stock recruitment was assumed to follow a Beverton-Holt relationship:

$$R = \frac{SSB}{SSB_0} / \left(1 - \frac{5h - 1}{4h} \left(1 - \frac{SSB}{SSB_0} \right) \right)$$

where *R* is the recruitment, *SSB* is the spawning stock biomass, *SSB*⁰ is the pre-exploitation equilibrium spawning stock biomass, and *h* is the steepness parameter, defined as the fraction of recruitment from the unfished population when the spawning stock biomass declines to 20% of its unfished level. Recruitment was fixed rather than estimated, as suggested for example by He *et al.* (2006) and Kenchington (2014) and the steepness parameter was assumed to be h = 0.75 (Myers *et al.* 1999, Punt *et al.* 2005, Dunn *et al.* 2006).

The initial year in the model was 1987, the first year of recorded data by the FIFD, and the model was run up to 2023. Projections from the model extended for another 35 years, up to 2058. Conditions in the initial year were assumed to be an equilibrium age structure at an unexploited equilibrium biomass (i.e., a constant recruitment assumption).

Within the model, each year's tagging event was included as an additional partition, i.e. the model kept account of the numbers of fish tagged in each year separately. The numbers of fish in the tagged component were modified by initial tag-related mortality (as a proportion) followed by a subsequent ongoing annual tag loss (at a constant rate). The population processes (natural mortality, fishing mortality, ageing, etc.) were then applied collectively over the tagged and untagged components of the model. The proportions-at-age of tagged fish were determined within the model by multiplying the observed proportions-at-length of tagged fish by the proportions of fish at age by length assumed by the model for the overall population (Mormede *et al.* 2014).

Estimation method

Model parameters were estimated by minimising the total objective function, which is the sum of the negative log-likelihoods from the observations, the negative-log Bayesian priors, and the penalties applied to constrain the parameterisations (see below). The estimated parameter values presented in the report are maximum posterior density (MPD) point estimates (Bull *et al.* 2012).

The posterior distribution of the parameters in a Bayesian analysis was estimated using the Monte-Carlo Markov Chain (MCMC) method. The starting point of each chain was the corresponding MPD estimate, the first 100,000 iterations were dismissed (burn-in), and every 1000th value was taken from the following 1,000,000 iterations. The resulting 1,000 values represent a systematic sample from the Bayesian posterior distribution for the parameter of interest. Chains were investigated for evidence of non-convergence using trace plots, chain autocorrelation plots, the single-chain stationarity test of Geweke (1992) and the stationarity and half-width tests of Heidelberger and Welch (1983).

Estimated parameters

Parameters estimated by the model, their priors, starting values and bounds are given in Table 4. Annual year class strengths (YCS) were estimated for 1986-2022, with the *Haist parameterisation* used to make the YCS parameters average to 1 over 1986-2017 (for the Haist method description, see Bull *et al.* 2012). The catchability coefficient (q) was estimated separately for the two longline fisheries. Uniform-log priors were considered appropriate for SSB₀ (Mormede *et al.* 2014, Ziegler and Welsford 2015) and q (Hillary *et al.* 2006, Ziegler and Welsford 2015), lognormal for YCS (Candy and Constable 2008, Ziegler and Welsford 2015), and uniform for selectivity parameters (Dunn and Hanchet 2010, Mormede *et al.* 2014).

| Estimated paran | neter | Ν | Prior | Start value | Lower bound | Upper bound |
|------------------|----------------|----|-------------|-------------|-------------|-------------|
| SSB ₀ | | 1 | uniform-log | 40,000 | 10,000 | 100,000 |
| YCS | | 37 | lognormal | 1 | 0.001 | 20 |
| Selectivity LLH | a 50 | 1 | uniform | 10 | 1 | 50 |
| | ato95 | 1 | uniform | 5 | 0.05 | 50 |
| Selectivity LLU | a 50 | 1 | uniform | 10 | 1 | 50 |
| | ato95 | 1 | uniform | 5 | 0.05 | 50 |

| q llh | | 1 | uniform-log | 1e-5 | 1e-9 | 0.1 |
| q 1.1.0 | | 1 | uniform-log | 1e-5 | 1e-9 | 0.1 |

Table 4. Number of parameters (N), priors, start values and bounds for free parameters estimated in the assessment model.

LLH - Spanish-system longline, LLU - umbrella-system longline, FIN - finfish trawl, LOL - calamari trawl, RFIN - groundfish survey, RLOL - calamari pre-season survey.

Time-invariant selectivity-at-age was estimated separately for each fishery and survey to reflect distinct age distributions of fish in the catch (i.e., assuming a fleets-as-areas approach). Logistic selectivity ogives were used for longline fisheries and double-normal for trawl fisheries and both surveys. Logistic ogive is defined by two parameters: a_{50} (age at 50% selectivity) and a_{to95} (difference in age at 50% and 95% selectivity), where the value of selectivity at age x is given by

$$f(x) = 1/[1 + 19^{(a_{50} - x)/a_{t095}}].$$

Double-normal ogive is defined by three parameters: a_1 (the mode), S_L (increasing left-hand limb shape parameter) and S_R (decreasing right-hand limb shape parameter), where the value of selectivity at age x is given by

$$f(x) = 2^{-[(x-a_1)/S_L]^2}, \quad (x \le a_1)$$

= 2^{-[(x-a_1)/S_R]^2}, \quad (x > a_1).

Penalties

Besides observations and priors, the final components of the objective function are penalties. The model included a catch limit penalty and vector average penalty. A catch limit penalty was applied to each fishery to ensure that the model doesn't estimate abundances so low that the recorded removals could not have been taken. A vector average penalty was used to encourage YCS to average 1. Penalty multipliers were set to 100 for catch limits and 20 for the YCS vector average penalty (for details on penalty calculations, see Bull *et al.* 2012).

Projections

Projections were carried out by running the model for 35 years into the future, using randomised recruitments and hypothetical catches. A total of 1000 simulations were run, each using the same (MPD) estimate of model parameters and the same hypothetical future catches (i.e. simulations differed only in terms of the randomised recruitments). The most recent (2021-2023) and future recruitments (2024-2058) were assumed log-normally distributed with standard deviation $\sigma_R = 0.6$. Future catch-split between fisheries was assumed from catch history and the current longline catch quota: umbrella-system longline = 1,040 t, finfish trawl = 300 t, and calamari trawl = 30 t.

Deterministic yield calculations

Deterministic MSY is the maximum constant annual catch (using the specified catch split) that can be sustained under deterministic recruitment (i.e. YCS = 1). The corresponding mortality rate is F_{MSY} , and the corresponding SSB is B_{MSY} . Simulations are run for different values of mortality F, starting from an unfished equilibrium state and running until the total annual catch C_F and spawning stock biomass SSB_F stabilize. CASAL searches over mortality rates F to find F_{MSY} , the value that maximizes C_F . Then MSY and B_{MSY} are C_F and SSB_F , respectively. The calculations are based on a single set of model parameters (i.e. MPD).

3. Results

3.1. Model fits

Diagnostics plots of model fit to observed data are provided in <u>Appendix 2</u>. The model fitted standardised CPUE data relatively well, i.e. it captured the declining overall trend for the Spanish system longline fishery and a more levelled trend for the umbrella-system longline fishery (Figure A.3). Corresponding trends in normalised residuals for both longline fisheries are shown in Figure A.4.

The model fit to catch-at-age data was good for all four fisheries and both research surveys (Figures A.5 - A.10). The corresponding residual bubble plots show no clear patterns, except for longline fisheries where the model consistently overestimated the proportion of 1-3 years old fish (Figure A.11). The model fit to the observed mean toothfish age was good in all cases except the Spanish system longline fishery (Figure A.12).

The model fit to tagging data was generally good; however, notable discrepancies occurred between the observed and expected recaptures of fish tagged in 2018 (the model overestimated the number of recaptures in 2019 and underestimated in 2021). That may be the result of (a) a comparatively large number of fish tagged in 2018 or (b) variation in the spatial overlap of tagging and fishing effort, in combination with low movement rates of fish (Figures A.13 - A.15).

Likelihood profiles were carried out by fixing SSB₀ over a range of plausible values (20,000 - 60,000 t) while the remaining parameters were estimated. CPUE for the Spanish system longline and recaptures of fish tagged in 2019 favoured lower biomass estimates. CAA for the Spanish system longline, calamari trawl fishery and the two surveys and recaptures of fish tagged in 2020 and 2022 found higher biomass estimates more likely. CPUE for the umbrella system longline, CAA for the umbrella system longline and finfish trawl fishery, and recaptures of fish tagged in 2016, 2017, 2018, and 2021 were at, or very close to, the MPD biomass estimate (Figures A.16, A.17).

MCMC trace plots showed no evident lack of convergence in estimated parameters, except for the left-hand limb shape parameter of double-normal selectivity curve for the calamari trawl fishery and both surveys (Figure A.18). The stationarity test of Geweke (1992) and the Heidelberger and Welch (1983) stationarity and half-width tests suggested failure to converge for the mentioned selectivity parameters (Table A.2) and autocorrelations in their MCMC samples were high, indicating slow mixing in MCMC chains (Figure A.19). Contributions to the objective function of each dataset, prior and penalty, are provided in <u>Appendix 3</u> (Table A.3).

3.2. Model estimates

MPD estimates (with MCMC 95% credible intervals) of initial spawning stock biomass (SSB₀), current spawning stock biomass (SSB₂₀₂₃) and current spawning stock biomass relative to SSB₀ (SSB₂₀₂₃/SSB₀) are given in Table 5. The current estimates of SSB₀, SSB_{current} and SSB_{current}/SSB₀ were higher than in the 2023 assessment by 5.8%, 10.3% and 4.9%, respectively. MCMC posterior distributions of SSB₀ and SSB₂₀₂₃/SSB₀ are given in Figure 5; since the inclusion of tag-recapture data into the model in the 2023 assessment, these posterior distributions were noticeably narrower and only slightly asymmetrical compared to the earlier years. Likelihood profiles suggest this is likely due to tag-recapture data being highly informative on the SSB₀. The estimated historical SSB trend up to 2023 is shown in Figure 6. Deterministic MSY was estimated at 1,699 t, in-between the 2023 and 2022 estimates (1,653 and 1,728 t, respectively).

Table 5. MPD estimates (and MCMC 95% credible intervals) of SSB₀, SSB₂₀₂₃ and SSB₂₀₂₃/SSB₀.

| SSB ₀ | SSB2023 | SSB2023/SSB0 |
|--------------------------|--------------------------|-----------------------|
| 25,942 (23,912 - 28,935) | 12,728 (10,815 - 15,878) | 0.491 (0.449 - 0.551) |

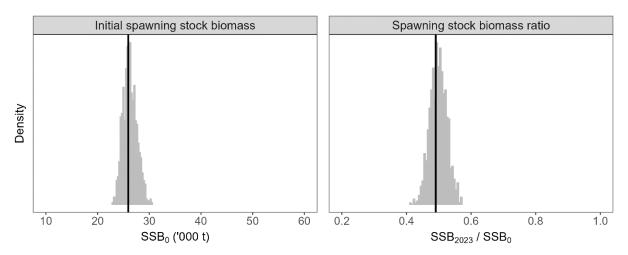

Figure 5. MCMC samples from posterior distribution of SSB₀ and SSB₂₀₂₃/SSB₀. Vertical black lines denote MPD point estimates.

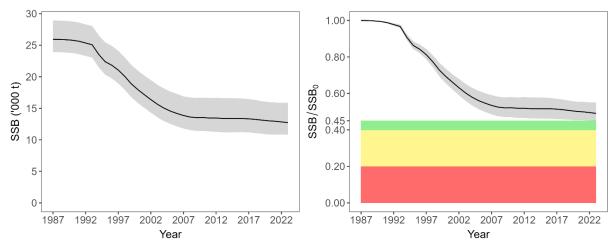

Figure 6. MPD estimate of the historical SSB trajectory; absolute on the left and relative to SSB₀ on the right (black line). Shaded areas denote MCMC 95% credible intervals of the model fit. Harvest control rule ranges are colour coded for reference: *target range* in green (SSB/SSB₀ = 0.45-0.40), *trigger range* in yellow (SSB/SSB₀ = 0.40-0.20) and *closure range* in red (SSB/SSB₀ < 0.20).

Estimated selectivity ogives appeared reasonable, in line with our knowledge of toothfish ontogenetic migrations and fishery interactions with the stock (Figure 7). The calamari trawl fishery catches the youngest fish; a combination of fishing in shallow waters (=only young fish is available) and using a small mesh size (=low gear selectivity), resulting in a selectivity described by the right limb of the assumed double-normal selectivity ogive. For the finfish trawl fishery (assumed double-normal) the model estimated maximum retention for 2-year-old fish and decreasing retention of younger (=escapes due to gear selectivity or not yet available at finfish trawl grounds) and older fish (=unavailable at trawling depths, i.e. moves to deeper waters). The two longline fisheries had almost identical selectivity curves (assumed logistic), catching predominantly older fish (=available in deeper waters). Survey selectivities were roughly comparable to commercial trawl fisheries, as surveys employ similar gear and cover similar grounds.

Year class strength estimates for the recent years (2015-2021) corresponded well to the recruitment estimates independent of the model (Lee *et al.* 2021, Skeljo 2023), with recruitment peaks in 2015 and 2017, followed by 4+ years of low recruitment (Figure 8). No independent survey data was available for the earlier years, making it difficult to confirm the YCS trend estimated in the model.

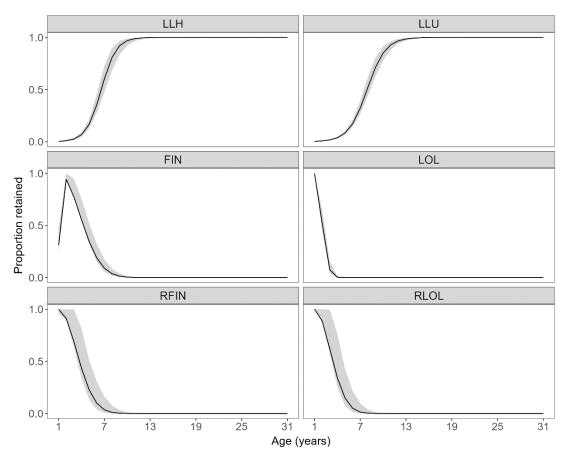

Figure 7. MPD estimate of selectivity ogives for four fisheries and two surveys (black lines). Shaded areas denote MCMC 95% credible intervals of the model fit.

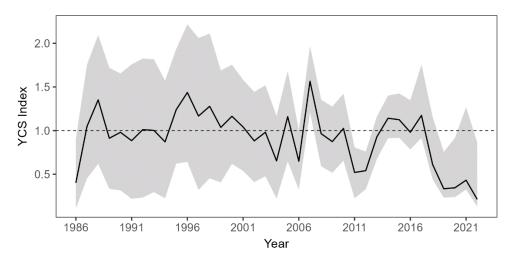

Figure 8. MPD estimate of year-class strengths in 1986-2022 (solid black line). Shaded area denotes MCMC 95% credible intervals of the model fit.

3.3. Model projections

Projections of SSB/SSB₀ under the assumption of random recruitments in 2021-2058 and constant annual catches in 2024-2058 are shown in Figure 9. The median SSB/SSB₀ is currently within the HCR *expansion range* but is projected to drop to the *target range* by 2029. Throughout the projection period, the median SSB/SSB₀ reaches a minimum of 0.44 in 2033 before increasing to 0.45 by 2045. The probability of the SSB/SSB₀ ratio falling below existing management thresholds, corresponding to the upper bounds of HCR ranges, was calculated for each year of the projection period as the proportion of the 1000 simulations below the respective threshold (Figure 10). The highest probability of falling below 0.45, 0.40 and 0.20 threshold during the projection period was estimated at 58%, 34% and 1%, respectively.

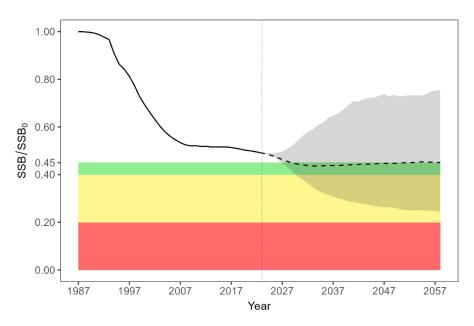

Figure 9. Future SSB/SSB₀ projections from the model MPD estimate. Shown are MPD estimate (solid black line), median of the projections (dashed black line), and 95% confidence intervals of the projections (shaded area). Harvest control rule ranges are colour coded for reference: *target range* in green (SSB/SSB₀ = 0.45-0.40), *trigger range* in yellow (SSB/SSB₀ = 0.40-0.20) and *closure range* in red (SSB/SSB₀ < 0.20).

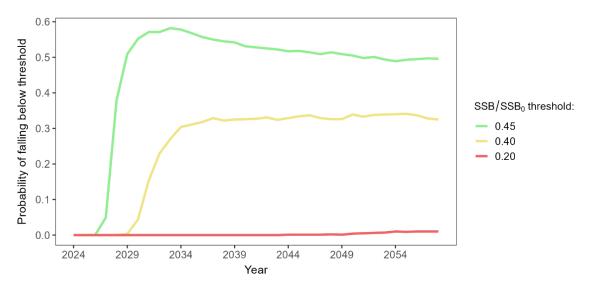

Figure 10. Probability of stock falling below designated SSB/SSB₀ management thresholds; based on projections.

4. Discussion

This report presents an updated integrated stock assessment for toothfish in Falkland Islands waters, using data up to the end of 2023. It is the second consecutive assessment where tag-recapture data were used as an index of absolute abundance, thus reducing model reliance on commercial CPUE data. Even though widely used as an index of relative abundance in stock assessment, shortcomings of commercial CPUE data are well known (Harley et al. 2001; Maunder and Punt 2004; Ye and Dennis 2009; Thorson et al. 2017; Maunder et al. 2006, 2020). Tag-recapture data are used routinely in toothfish stock assessments in CCAMLR waters; assessments for South Georgia, South Sandwich Islands, Heard and McDonald Islands, Kerguelen, Crozet Island, and Ross Sea all use extensive longterm tag-recapture datasets (Earl and Readdy 2023; Readdy and Earl 2023; Masere and Ziegler 2023; Massiot-Granier et al. 2023a, 2023b; Mormede et al. 2023). In comparison, the Falkland Islands toothfish tagging programme is still in development; it commenced in 2016, but the tagging effort varied widely over time. The initial goal of tagging 3000 fish was achieved in 2016-2018, followed by a considerable decrease in tagging efforts in 2019-2020. The programme has been expanded and extended as a long-term protocol in 2021, aiming to tag ~1000 fish annually (roughly one fish per tonne of TAC) to support the stock assessment. The current stock assessment was informed by ~5500 releases and ~380 recaptures (once within-year and out-of-zone recaptures were excluded). These numbers are still low, but future assessments will benefit from the extended tagging protocol, and updating the model with new tag-recapture data has become a routine task now that R and CASAL codes have been established.

Compared to the previous year, the current assessment resulted in somewhat higher estimates of SSB₀, SSB_{current} and SSB_{current}/SSB₀. As there were no major changes to the model structure or assumptions from the previous year, the change in estimates was largely due to data updates through 2023. The effect of different datasets was explored by successively excluding all possible combinations of CPUE, CAA, and tag recapture data for 2023 and re-running the model. The comparison indicated that more optimistic estimates were driven primarily by tag recaptures in 2023, while the CPUE index and CAA for 2023 had comparatively little effect on changing model estimates from the year before. Changes to input parameters (Von Bertalanffy growth parameters, lengthweight coefficients, maturity vector, tag shedding and tag emigration rates) due to data updates were minimal and had a negligible effect on model estimates.

Projections from the current and the previous assessments showed a similar trend, except the current assessment projected SSB/SSB₀ to drop from the *expansion range* to the *target range* three years later, in 2029 instead of 2026. This change can be explained by a higher MPD estimate of SSB_{current}/SSB₀ in the current model. The MPD estimate was the starting point for the projections, and everything else being the same, it would take projected SSB/SSB₀ longer to drop below 0.45 when starting from a higher SSB_{current}/SSB₀ value. The projected drop in SSB/SSB₀ is a response to a series of weak recruitments estimated by the model (below-average YCS in 2018-2020) and supported by an independent analysis (Lee et al. 2021). Running alternative projections starting from 2019, 2020, 2021, 2022 or 2023, i.e. following one to five consecutive years of weak recruitment, showed that extended periods of weak recruitment lead to increasingly pessimistic SSB/SSB₀ projections. The current projections assumed model-estimated YCS up to and including 2020 (i.e. the YCS time series used in projections ended with three years of weak recruitment) and random YCS from 2021 onwards. We assumed random YCS for 2021 and 2022 instead of model-estimated values because of limited information on the most recent recruitments available to the model (a common approach; see Masere and Ziegler 2023). For example, if a strong toothfish recruitment occurred in an area not covered by the calamari trawl fishery or surveys (e.g. on the west or southwest Falkland Islands Shelf), it might take a few years before this fish appears in the catches; only then the information on strong recruitment would become available to the model via a peak in CAA data for 2- or 3-year-old fish. As a precaution, an alternative model run assumed model-estimated YCS up to and including 2021 (i.e. the YCS time series used in projections ended with four instead of three years of weak recruitment)

and random YCS from 2022 onwards. The median of SSB/SSB₀ projections was less optimistic in this case but remained within the *target range* during the projection period.

Given the influence of recent recruitment strengths on model projections, close monitoring of juvenile toothfish abundance during research surveys needs to be emphasized. Protection of high recruitment age-0 cohorts while on the shelf via spatiotemporal management of calamari trawl fishery has been proposed (Skeljo 2023), and a protocol established in early 2024.

Currently, FIFD is conducting a dedicated project on toothfish reproductive traits in Falkland Islands waters, aiming to revise the current maturity-at-age data and provide insight into the prevalence of skipped spawning in females. Once available, these data will be introduced to the stock assessment.

5. Management advice

Management advice is based on the harvest control rules (HCR) established for the Falkland Islands toothfish longline fishery (Farrugia and Winter 2018) (Appendix 4). The estimated SSB₂₀₂₃/SSB₀ ratio of 0.491 was above the *upper target reference point* (0.45), i.e. in the *expansion range*; projections from the current model indicated that SSB/SSB₀ ratio will drop and remain in the *target range* during 2029-2045. The year 2023 was the fourth consecutive year with SSB_{current}/SSB₀ estimated to be in the *expansion range*; however, since SSB/SSB₀ projections under the current TAC showed a decrease below 0.45 within ten years, no alteration of TAC was anticipated by HCR at this point.

The recommendation is to maintain toothfish annual TAC in the longline fishery at its current level of 1,040 tonnes.

Appendix 1. CPUE standardization

CPUE was standardized using Generalized Linear Mixed Models (GLMMs; Pinheiro and Bates 2000); GLMMs were fitted using package glmmTMB (Brooks *et al.* 2017, Magnusson *et al.* 2017) implemented in R version 4.1.3 (R Core Team, 2022). Before modelling, data were explored following the protocol described by Zuur *et al.* (2010); explanatory variables were inspected for outliers and collinearity using visual assessments, Pearson correlation coefficients (>0.5) and variance inflation factors (>3). Continuous explanatory variables were presumed to represent erroneous entries or broken sets and excluded from the analysis (1.2% of days for the Spanish system and 0.01% of lines for the umbrella system fishery).

The response variable was defined as toothfish CPUE expressed in kg-per-hook per day (Spanish system) or kg-per-umbrella per line (umbrella system) and modelled using Gamma distribution with a log link function. The explanatory variables considered in the model as either fixed or random effects are given in Table A.1.

| Explanatory variabl | es | - Variable type | Effect | |
|---------------------|--------------------------------|-----------------|--------|--|
| Spanish-system | Spanish-system umbrella-system | | Ellect | |
| Year* | Year* | Categorical | Fixed | |
| Month* | Month* | Categorical | Random | |
| Area* | Area* | Categorical | Random | |
| Depth | Depth* | Continuous | Fixed | |
| Soak-time | Soak-time* | Continuous | Fixed | |
| Vessel* | - | Categorical | Random | |
| - | Hooks-per-umbrella | Categorical | Fixed | |

Table A.1. Explanatory variables considered in the CPUE standardization.

* Variables included in the final model.

The Year effect is the quantity of interest and had to be included in the final model; the remaining explanatory variables were added to the Year by forward stepwise selection and included in the final model only if they improved pseudo- R^2 by at least 0.5%. Pseudo- R^2 was calculated based on the likelihood-ratio test, as implemented in the R package MuMIn (Barton 2009). The Month and Area variables were treated as random effects, attempting to capture temporal or spatial dependency in CPUE; the spatial resolution was 1° Lon x 1° Lat. The *Depth* variable is the average fishing depth of each line (umbrella system) or the average fishing depth of multiple lines set in a day and belonging to a single response CPUE value (Spanish system). The Soak-time is the soak time of each line (umbrella system) or soak time of multiple lines set in a day and belonging to a single response CPUE value (Spanish system). The Vessel variable was treated as a random effect in the Spanish-system standardization to account for dependence in CPUE values belonging to the same vessel due to e.g. vessel fishing power and skipper/crew skills and behaviour. The Vessel variable was excluded from the umbrella-system CPUE standardization because only two vessels appeared in the model (too few to treat it as a random effect) and never fished concurrently in a year, making the Vessel and Year effect indistinguishable. The umbrella system had an additional variable, the number of Hooks-per-umbrella, which progressively decreased from 10 hooks initially to 8 hooks in December 2007, to 7 hooks in March 2014, and 6 hooks in June 2016).

The final GLMM fitted to the Spanish-system data included *Year* as a fixed effect and *Month*, *Region* and *Vessel* as random effects; the model explained 19.7% of the overall variation in CPUE. Standardized and unstandardized CPUE time series had similar declining trends (Figure A.1). The final GLMM fitted to the umbrella-system data included *Year*, *Soak-time* and *Depth* as fixed effects and

Month and *Region* as random effects; the model explained 16.5% of the overall variation in CPUE. Standardized and unstandardized CPUE time series were similar and lacked a clear trend (Figure A.2).

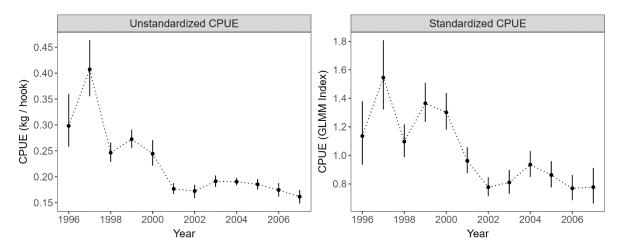

Figure A.1. Spanish-system longline fishery unstandardized and standardized CPUE time series; black vertical lines denote 95% confidence intervals.

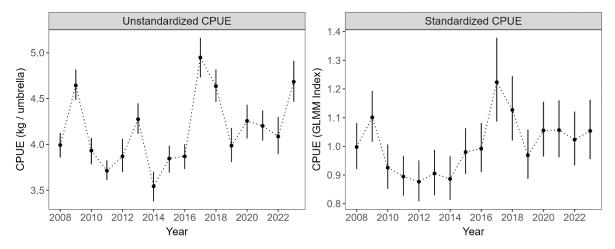

Figure A.2. Umbrella-system longline fishery unstandardized and standardized CPUE time series; black vertical lines denote 95% confidence intervals.

Appendix 2. Diagnostics plots

Figure A.3. MPD model fit (black line) to standardised CPUE indices for Spanish-system (blue dots) and umbrellasystem longline (green dots); Vertical blue and green lines denote 95% confidence intervals of standardised CPUE indices; shaded areas denote MCMC 95% credible intervals of model fit.

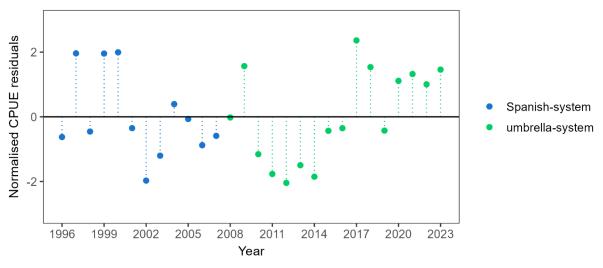

Figure A.4. Normalised residuals from model fit to standardized CPUE time series; for Spanish-system (blue) and umbrella-system longline (green).

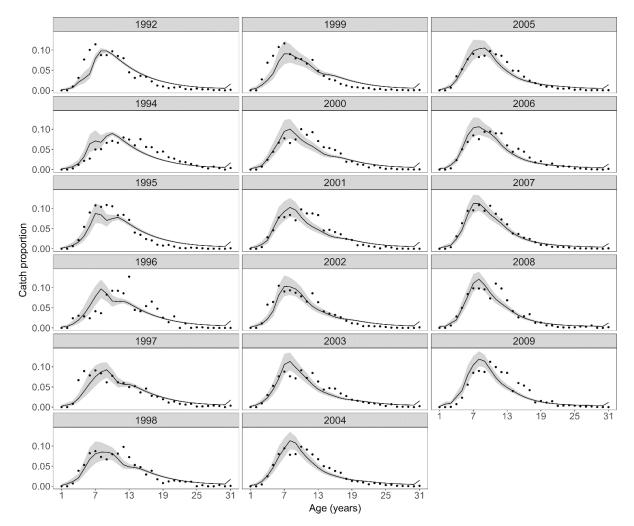

Figure A.5. MPD model fit (solid lines) to observed catch-at-age for Spanish-system longline fishery (dots); shaded areas denote MCMC 95% credible intervals of the fit.

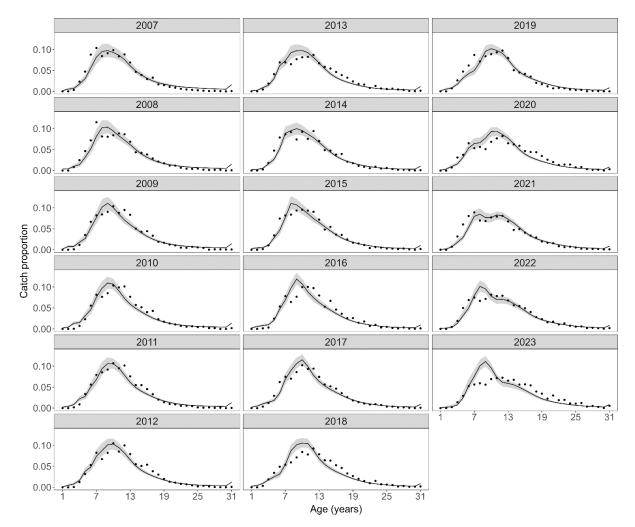

Figure A.6. MPD model fit (solid lines) to observed catch-at-age for umbrella-system longline fishery (dots); shaded areas denote MCMC 95% credible intervals of the fit.

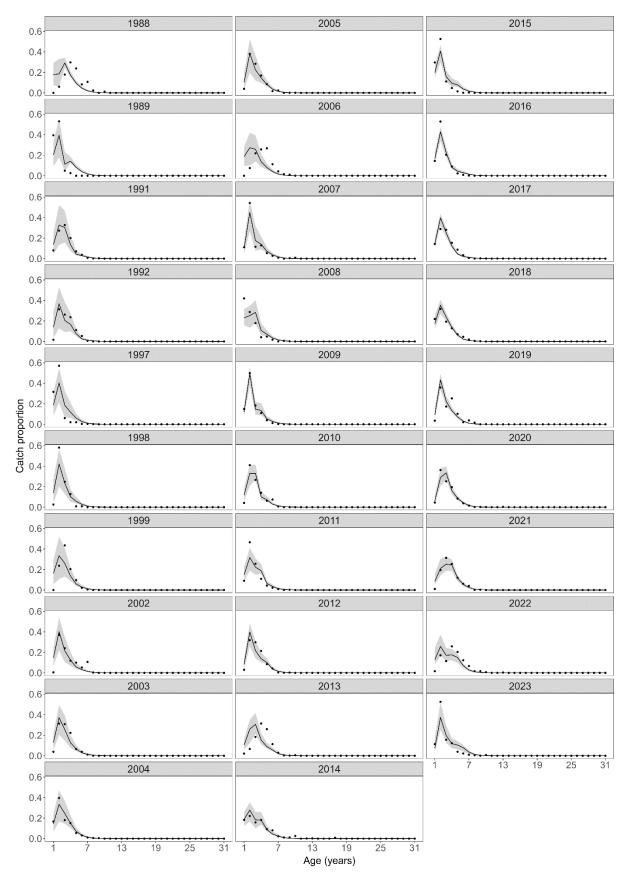

Figure A.7. MPD model fit (solid lines) to observed catch-at-age for finfish trawl fishery (dots); shaded areas denote MCMC 95% credible intervals of the fit.

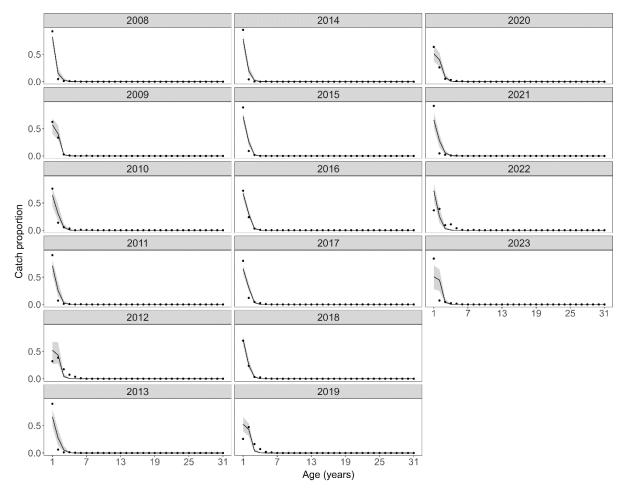

Figure A.8. MPD model fit (solid lines) to observed catch-at-age for calamari trawl fishery (dots); shaded areas denote MCMC 95% credible intervals of the fit.

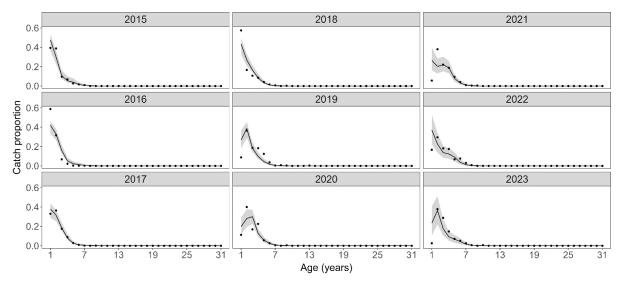

Figure A.9. MPD model fit (solid lines) to observed catch-at-age for groundfish survey (dots); shaded areas denote MCMC 95% credible intervals of the fit.

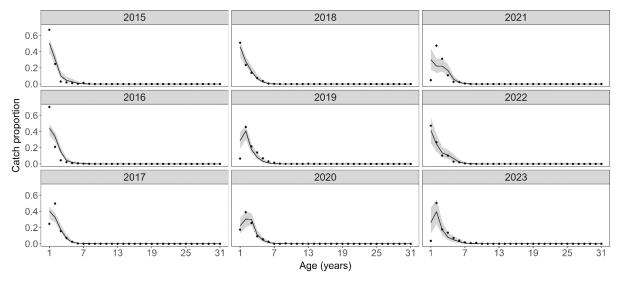

Figure A.10. MPD model fit (solid lines) to observed catch-at-age for calamari pre-season survey (dots); shaded areas denote MCMC 95% credible intervals of the fit.

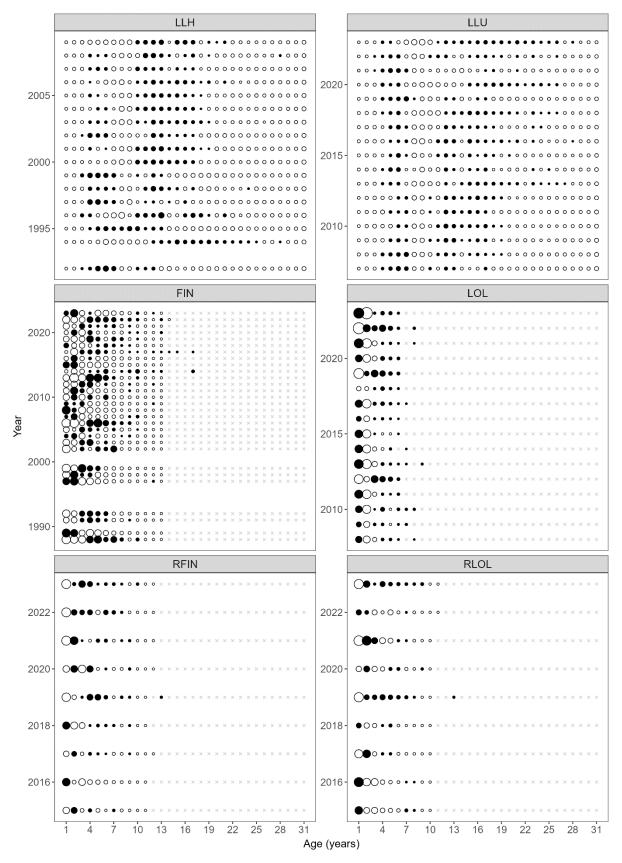

Figure A.11. Residuals from the model fit to observed catch-at-age for four fisheries and two research surveys. Bubble size is relative to the absolute residual value; positive residuals are denoted by full circles, and negative by empty circles.

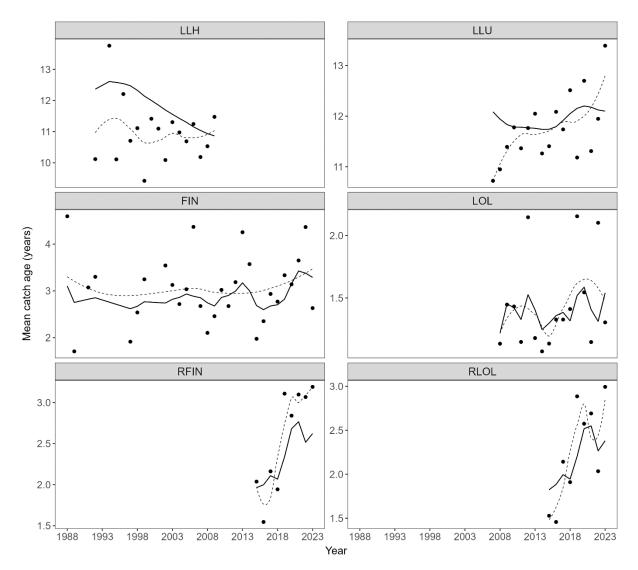

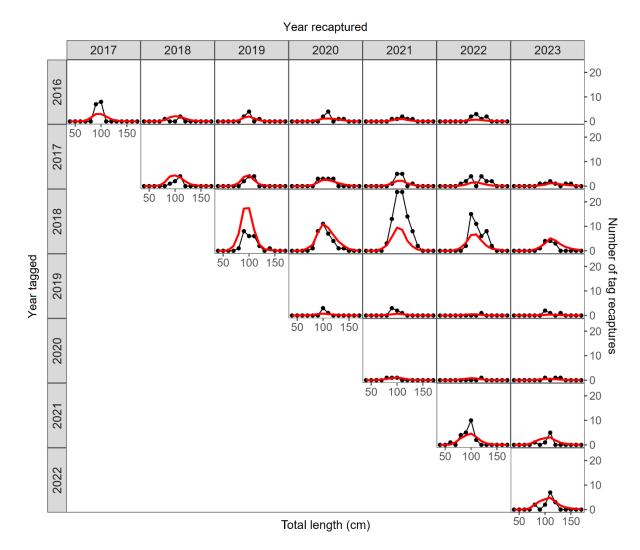

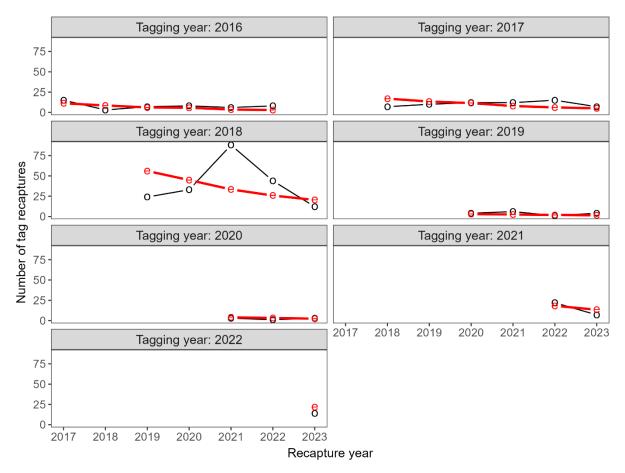

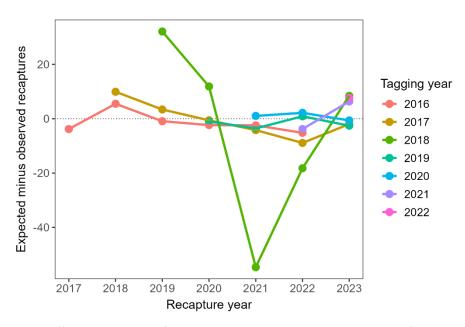

Figure A.12. Model fit (solid lines) to observed mean age-at-capture for four fisheries and two research surveys (black dots); loess smoothers with span = 0.75 (dashed lines) are added to aid visual interpretation of trends in the observed data.

A.13. Model fit (red lines) to observed tag recapture numbers by 10 cm length bins (black dots); for tag releases in 2016-2022 and tag recaptures in 2017-2023. Recaptures after six years at liberty were excluded from the model and the plot.

A.14. Model fit (red lines) to observed tag recapture numbers (black dots); for tag releases in 2016-2022 and tag recaptures in 2017-2023. Recaptures after six years at liberty were excluded from the model and the plot.

A.15. Differences between fitted and observed tag recapture numbers; for tag releases in 2016-2022 and tag recaptures in 2017-2023. Recaptures after six years at liberty were excluded from the model and the plot.

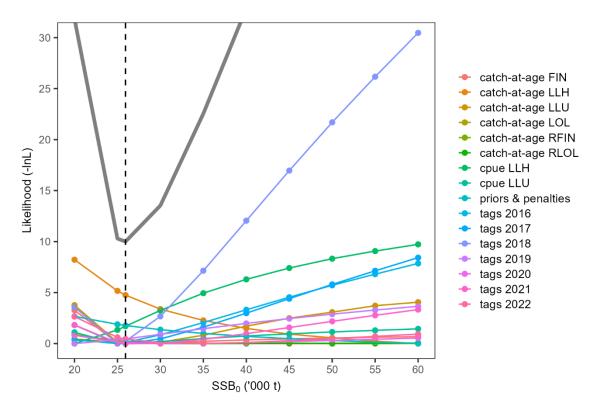

Figure A.16. Likelihood profiles for SSB₀. Negative log-likelihood values for individual datasets were rescaled to a minimum of zero, while the total objective function was rescaled to a minimum of 10 for easier visualisation (solid grey line). The dashed vertical line denotes the MPD estimate of SSB₀. LLH - Spanish-system longline, LLU - umbrella-system longline, FIN - finfish trawl, LOL - calamari trawl, RFIN - groundfish survey, RLOL - calamari pre-season survey.

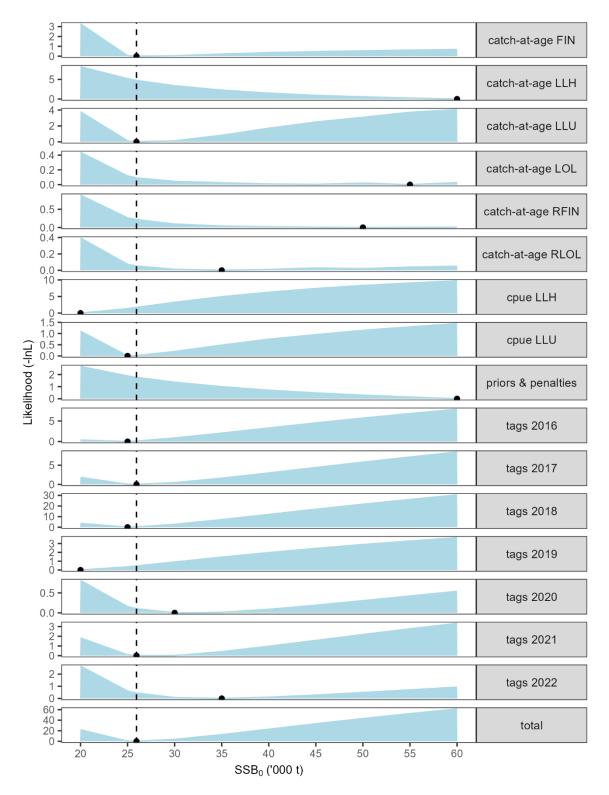

Figure A.17. Likelihood profiles for SSB₀. Negative log-likelihood values for individual datasets and the total objective function were rescaled to a minimum of zero. The dashed vertical line denotes the MPD estimate of SSB₀; dots denote SSB₀ values with the minimum negative log-likelihood value for each dataset. LLH - Spanish-system longline, LLU - umbrella-system longline, FIN - finfish trawl, LOL - calamari trawl, RFIN - groundfish survey, RLOL - calamari pre-season survey.

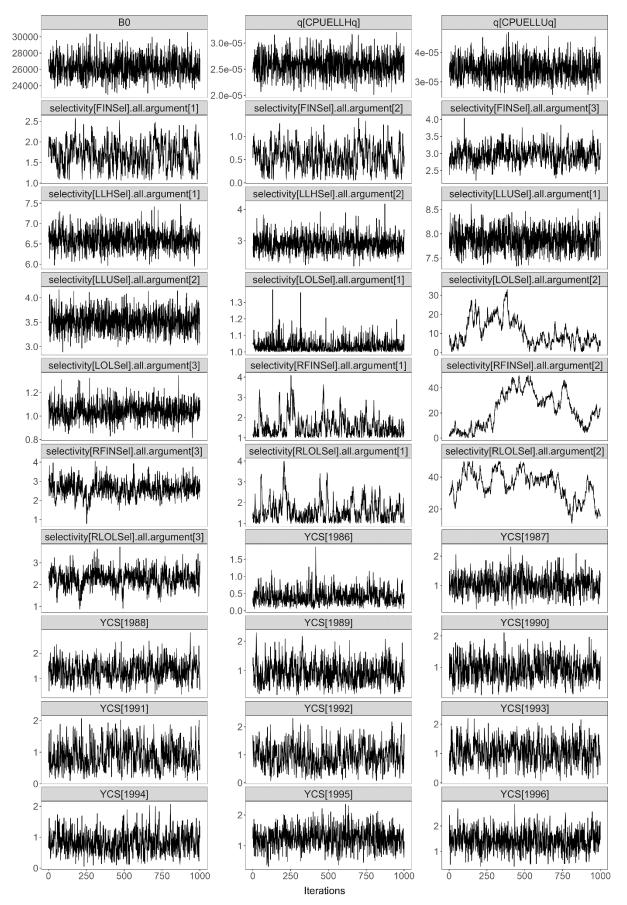

Figure A.18. MCMC posterior trace plots for all estimated parameters (figure 1 of 2).

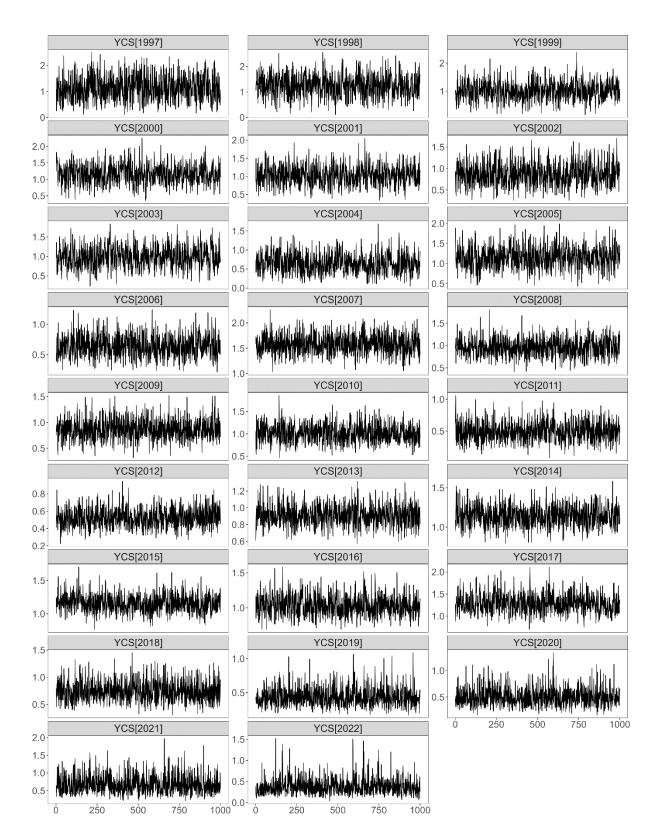

Figure A.18. Continued (figure 2 of 2).

Table A.2. MCMC convergence diagnostic results: Geweke's single-chain stationarity test and Heidelberger and Welch's stationarity and half-width tests.

LLH - Spanish-system longline, LLU - umbrella-system longline, FIN - finfish trawl, LOL - calamari trawl, RFIN - groundfish survey, RLOL - calamari pre-season survey.

Appendix 4. Harvest control rules

Based on the CASAL model output, the following decision matrix of harvest control rules has been established to manage the Falkland Islands toothfish longline fishery (Farrugia and Winter 2018):

- 1. <u>Expansion range</u>: If the ratio of SSB_{current}/SSB₀ has remained above the upper target reference point (45%) for 3 consecutive years and the SSB projection with the current TAC shows no decrease below 45% for at least 10 years (one generation) under precautionary assumptions, the Director may authorize an increase in longline TAC to a level that continues to show no projected SSB_{current}/SSB₀ decrease to below 40% (trigger point) for at least 10 years under precautionary assumptions.
- 2. <u>Target range</u>: If the ratio of SSB_{current}/SSB₀ is between 40% and 45% (within the target range), current longline TAC is reviewed in relation to stock trends. Current TAC may be maintained if SSB_{current}/SSB₀ has increased from the previous assessment, or if the SSB ratio projection shows a level status under precautionary assumptions. TAC may not be increased, but it may be decreased in response to substantial indications of unfavourable conditions for the stock.
- <u>Trigger point and range</u>: If the ratio of SSB_{current}/SSB₀ falls to ≤ 40% (trigger point), longline TAC will be decreased to a level that projects an increasing SSB trend under precautionary assumptions. The magnitude of the proposed TAC reduction will be examined using three methods (adapted from ICES, 2017):
 - a. Indexed to the reduction of the MSY estimates:
 - $TAC_{vear} = TAC_{vear-1} * (MSY_{vear}/MSY_{vear-1})$
 - b. Indexed to the reduction of the SSB estimates:
 - $TAC_{year} = TAC_{year-1} * (SSB_{year}/SSB_{year-1})$
 - c. Indexed to the reduction in SSB ratios:

 $TAC_{year} = TAC_{year-1} * (SSB \ ratio_{year}/SSB \ ratio_{year-1})$

TACs obtained from all three methods will be projected forward in the stock assessment model and the trends in SSB will be compared. The final method will be chosen based on it returning the SSB ratio to above 40% within 10 years (one generation) of the SSB ratio falling below 40%. If more than one method meets this requirement, the chosen method will also depend on discussions between the Fisheries Department and the industry.

4. <u>Limit reference point</u>: If the ratio of SSB_{current}/SSB₀ is ≤ 20%, the longline fishery will be closed pending a comprehensive evaluation of conditions required to rebuild the stock. The Director may authorize test fishing to measure the biological parameters of the stock, subject to close monitoring by the Fisheries Department.
